Background and Aim: Use of fluoride releasing materials to decrease the risk of demineralization around orthodontic brackets would be reasonable as an adhesive for bracket bonding only if they provide acceptable shear bond strength (SBS). The aim of this study was to evaluate the SBS of resin-modified glassionomer cements (RMGICs) modified by nano-zinc oxide (NZnO) and nano-hydroxyapatite (NHA) in comparison with composite resins.

Materials and Methods: In this experimental study, 80 extracted human premolars were used. The teeth were randomly divided into 4 groups as follows: Group 1: Transbond XT as a control group, Group 2: RMGIC (Fujii II LC), Group 3: RMGIC with 5% NHA and Group 4: RMGIC with 2% NZnO. After etching the enamel, brackets were bonded. The SBS was measured for each group. The percentage of adhesive remnants on the enamel surface was quantified using the adhesive remnant index (ARI). The data were analyzed using one-way ANOVA and the Kruskal Wallis test.

Results: According to the results of ANOVA, no significant difference was found in the SBS of groups (p=0.075). The mean shear bond strength in groups 1 to 4 was 15.43±4.61, 14.95±4.34, 17.97±3.65 and 17.08±3.59, respectively. According to the Kruskal-Wallis test, there was no significant difference in ARI score among the groups (p=0.413).

Conclusion: The amount of SBS was similar among all groups and addition of NZnO and NHA particles had no negative effect on SBS of RMGIC. Less than half the adhesive remained on the enamel surface after bond failure in all groups.

Abstract

Introduction

Nowadays, composite resins are commonly used by orthodontists because they allow easy manipulation and reduce the time of bracket placement [1]. One of the most important shortcomings of composite resins is their lack of fluoride release; thus, they cannot impede enamel demineralization around brackets [2]. Glass Ionomer Cements (GICs) were first introduced by Wilson and Kentin1972 for anterior tooth restorations [3]. In addition to biocompatibility with the enamel and dentin, they have a cariostatic effect and they promote remineralization by releasing fluoride [4]. Some in vitro and in vivo studies have reported that GICs have weak clinical bond strength; thus they are not recommended for routine clinical orthodontic
bracket bonding [5]. In an attempt to improve bond strength, RMGICs were developed [4]. RMGICs are composed of glass-ionomer (fluoroaluminosilicate glasses and polyacrylic acid) and composite resins (photo or chemical initiators and methacrylate monomers) [6]. The incorporation of resin improved bond strength to the enamel surface [4]. They also have less technical sensitivity and better physical and mechanical properties than conventional GICs [7] but the amount of released fluoride is similar to that of conventional GICs [8].

Different techniques have been introduced to improve the properties of RMGICs. Addition of zinc oxide (ZnO) particles to RMGIs is among these techniques [9]. ZnO has been used for several years in dentistry due to its biocompatibility and antimicrobial effect [10].

Zinc serves as an activator of enzymes. It can be toxic to microorganisms at low concentrations and can inhibit plaque accumulation at high concentrations. Addition of ZnO particles to RMGICs increases their antimicrobial efficacy with no negative effect on their SBS [9].

By decreasing the particle size of ZnO to nanometer, the antimicrobial effect of composite resins, which contain this particle increases significantly [11]. In addition to increased antimicrobial activity, NZnO particles improve physical properties and flexural strength of GICs, because these particles bond to polyacrylic liquid of GICs [12]. Hydroxyapatite is a type of calcium phosphate, which is the main mineral component of the enamel; it also constitutes more than 60% of dentine by weight. In addition, hydroxyl apatite constitutes the inorganic matrix of human bone. The ability of hydroxyapatite to integrate with bone structure can help the bond between bone and implant [13]. As hydroxyapatite particles and inorganic ions infiltrate into the demineralized surfacethey impede the movement of calcium released from the enamel surface; therefore, resistance to demineralization is intensified [14]. GICs have been found to interact with hydroxyapatite via the carboxylate groups in the polyacid. Therefore, the incorporation of HA into GICs may not only improve the biocompatibility of GICs but also have the potential of enhancing their mechanical properties. In addition, it has the ability to increase the bond strength to tooth structure due to its similar composition and structure to enamel and dentin [15]. One of the most important characteristics of bonding agents used in orthodontics is their SBS. Adding nano particles to RMGICs will be acceptable only if they do not have a negative effect on SBS; thus, evaluation of SBS of cements, which contain these nano particles is very important. The aim of this study was to evaluate the SBS of RMGICs modified by NHA and NZnO metal brackets in comparison with composite resin.

Materials and Methods

In this experimental study, 80 sound premolar teeth without cracks, restorations or decalcifications were collected. The teeth were cleaned from calculus and tissue debris and then buccal surfaces of all teeth were polished using a rubber cup operated at low speed and pumice powder for 10 seconds. After extraction, all teeth were stored in distilled water at room temperature for about 3 months. The teeth were randomly divided into 4 groups of 20. All the samples were blindly prepared as follows in two consecutive days by the same operators specifically trained for this purpose.

The composition of materials used in this study is shown in Table 1.

The teeth were randomly divided into 4 groups as follows:

- **Group 1**: Transbond XT (TBXT) (3M ESPE, St. Paul, MN, USA)
- **Group 2**: Fuji II LC (RMGIC) (GC Corp. Tokyo, Japan)
- **Group 3**: Fuji II LC (RMGIC) (GC Corp. Tokyo, Japan) containing %5 NHA
- **Group 4**: Fuji II LC (RMGIC) (GC Corp. Tokyo, Japan) containing %2 NZnO

In this study, NZnO particles with grain size of 20-40 nm and purity of more than 99.7% and NHA particles with grain size of 50 nm and purity of 90% obtained from Nanoshelwere added to RMGIC. After weighing of nanoparticles by a digital scale (IranTaraz, Tehran, Iran), particles were mixed with RMGIC powder by means of mortar and pestle. In group 1, after cleaning, the buccal surfaces of the teeth were etched with 37% phosphoric acid (Ultraetch, Ultradent, South Jordan, USA) for 30 seconds, washed for 10 seconds and dried with gentle flow of air.

* Both formulations of RMGIC plus 2%NZnO and RMGIC plus 5%NHA were prepared at Shahed University of Medical Sciences, Faculty of Dental Science. Registration number 76918 for RMGIC +2%NZnO and 75084 for RMGIC +5%NHA.
A thin layer of TBXTPrimer(3M ESPE, St. Paul, MN, USA) was applied on the buccal surfaces of an applicator and then cured for 10 seconds using a LED light curing unit (L.E. Demetron, SDS Kerr, Orange, USA) with a wavelength of 470nm and light intensity of 1100mW/cm². Composite resin (Transbond XT, 3M Unitek, Monrovia, Calif) was then applied on the base of brackets and brackets were placed at the center of the buccal surfaces using an bracket positioner. Excess adhesive was removed and finally the bonding material was cured for 40 seconds (10 seconds from each side).

In group 2, after cleaning, the buccal surfaces of the teeth were etched with 37% phosphoric acid for 30 seconds, washed for 10 seconds and dried with gentle flow of air. According to the manufacturer's instructions, 1 scoop of powder was mixed with 2 drops of liquid, with 3.2 to 1 ratio. The powder was divided into 2 parts and each part was mixed with liquid by a plastic spatula for 10 seconds. RMGIC was then applied on the base of brackets and brackets were placed at the center of the buccal surfaces using a bracket positioner. Excess adhesive was removed and finally the bonding agent was cured for 40 seconds (10 seconds from each side).

Next, 5% NHA powder and 2% NZnO powder were added to the RMGIC powder in groups 3 and 4, respectively. Brackets were placed at the center of the buccal surfaces as in group 2. The specimens were mounted and incubated at 37°C in distilled water bath for 24 hours [16]. For assessment of the SBS, a chisel-shaped rod with 0.5 mm thickness was attached to the head of the Instron universal testing machine (Zwick-Roell, Ulm, Germany) and shear force was applied at a crosshead speed of 1mm/min as close to the bracket-tooth interface as possible in incisal–cervical direction. The load at failure was recorded using the testXpert V11.0-software (Zwick-Roell, Ulm, Germany) and reported in megapascals (Mpa). Following debonding, each tooth was examined under a stereomicroscope (Carton Optical Industries, Bangkok, Thailand) at ×10 magnification. The percentage of adhesive remained on the enamel surface was quantified according to the values of the adhesive remnant index (ARI) previously described by Artun and Bergland [17] as follows:

0: No adhesive remained on the enamel surface.
1: Less than 50% of adhesive remained on the enamel.
2: More than 50% of adhesive was left on the enamel.
3: The entire adhesive remained on the tooth structure.

In this study, data were analyzed using SPSS software (version 20) (Microsoft, IL, USA). In all groups, SBS was analyzed using one-way ANOVA. The Kruskal-Wallis test was used to compare the ARI scores among the 4 groups. p<0.05 was considered statistically significant.

### Results

The bond strength values (in MPa) and standard deviations (SD) are shown in Table 2. The results of one-way ANOVA showed that there was no significant difference in SBS among the 4 groups (p=0.075). Furthermore, addition of NHA and NZnO particles to RMGICs had no negative effect on SBS of RMGICs compared to composite resins.

Distribution of the modes of failure (ARI scores) is shown in Table 3. The Kruskal-Wallis test showed that there was no significant difference in ARI scores among the 4 groups (p=0.413).

In all groups, ARI type 1 had the highest frequency (less than 50% of adhesive remained on the enamel surface).

### Discussion

In spite of the advances made in the field of orthodontics, a basic issue has not yet been completely resolved, that is, the increasing risk of

*Spring 2015; Vol. 27, No. 2*
developing WSLs around orthodontic brackets. Some studies have shown that more than 50% of the patients undergoing orthodontic treatment develop WSLs. The most efficient clinical approach described in the literature to minimize the risk of occurrence of these lesions has been bracket bonding with GICs. However, orthodontists are still reluctant to use this cement particularly due to technique sensitivity and concerns regarding the SBS [4].

Mitran introduced RMGIC as a hybrid material in 1991 [18]. RMGICs have been developed to combine the desirable properties (such as high SBS) of composite resins and fluoride release potential of GICs. The manufacturer’s instruction for RMGICs is to use 10% polyacrylic acid as enamel conditioner and light curing for 40 seconds. Because of high rate of bond failure compared with composite resins, some authors have proposed different bonding protocols to increase the SBS, such as etching with 37% phosphoric acid or increasing the duration of light curing. Maruo et al. indicated that SBS of RMGICs was enhanced by the use of 37% phosphoric acid in comparison with 10% polyacrylic acid; but increasing the light curing duration had no significant effect on SBS [19].

Previous studies indicated that RMGICs exhibited SBS values similar to those of composite resin when phosphoric acid was used for etching [16]. In the current study, we used 37% phosphoric acid and there was no difference in SBS between RMGIC and composite resin similar to the findings of previous studies. In contrast, in absence of etching, the SBS achieved with RMGIC was significantly lower than that of conventional composite resin [20].

Khourishi et al. assessed the effect of pre-conditioning with phosphoric acid on SBS of three different RMGICs and concluded that the effect of acid pre-conditioning on SBS was material-dependent and only SBS of Fuji II LC increased due to etching. Safaralizadeh and Rezvan showed that adding 2% N\textsubscript{2}H\textsubscript{4}O\textsubscript{3} to RMGIC significantly increased the fluoride releasing potential and improved the cariostatic effect of RMGICs. Malekhoseinian and Rezvan also observed that adding 2% N\textsubscript{2}H\textsubscript{4}O\textsubscript{3} not only increased flexural strength and flexural elastic modulus of RMGICs but also inhibited the growth of Streptococcus mutans [21].

According to the results of the current study, adding 2% N\textsubscript{2}H\textsubscript{4}O\textsubscript{3} had no negative effect on SBS of RMGICs. Jatania and Shivalinga observed that the concentration of N\textsubscript{2}H\textsubscript{4}O\textsubscript{3} in RMGIC increased, antimicrobial effect wasehanced but the SBS decreased [22]. This finding is not in agreement with our results. Three reasons can be proposed for this controversy:

1. ZnO nanoparticles which have superior properties compared to ZnO particles [11, 12] were not used in their study; 2- In the two groups containing zinc oxide, larger than normal amount of RMGIC liquid was used, which might have weakened the material and 3- The blade used in their study applied the force closer to the tie wing rather than the base [23]. Klocke and Kahl-Nieke demonstrated that variations in the direction of deboning force significantly influence the SBS measurement. Changes in the direction of the shearing force as small as 15° can decrease the bond strength values by 27.4% [24].

Mohammadi Basir et al. observed that incorporating 5% NHA into RMGIC did not decrease the compressive strength enhancement occurred with addition of 5 wt% NHA [25]. Seyedtabai and Nurisar reported that RMGIC plus 5% NHA had no negative effect while adding 10% NHA significantly lowered the SBS. Therefore, we used 5 wt% NHA to evaluate its effect on SBS to metal brackets. According to the results of the current study, adding 5% NHA had no negative effect on SBS of RMGICs. Researchers have also shown that incorporating NHA into GICs increases the demineralization resistance more effectively than HA [14, 15]. This may be related to the smaller particle size of NHA, which enhances its deposition into micro-pores in demineralized enamel. In addition, high solubility of NHA leads to efficient release of calcium and phosphate ions, which fill the demineralized micro-pores [26].

The ARI score for the debonded interfaces of composite resin was mainly 1 (60% of specimens) in our study; therefore, most failures occurred at the composite/ enamel interface. A disagreement exists in this regard among different studies; some studies reported the highest frequency of failures at
the composite/enamel interface with the greatest composite remnants on the base of brackets [16];while others reported the highest frequency of failures at the composite/bracket interface with the greatest amount of composite remnant on the enamel surface [4,20].Our results also showed that the score for the debonded interfaces of RMGICs and RMGIC plus5% NHA wasmainly 1 (70% and 60% of specimens,respectively); thus, in these two groups the highest frequency of bond failures occurred at the adhesive/enamel interface. For RMGIC plus2% NZnO, ARI score in 50% of specimens was 1, and it was 2 and 3 for the remainder, which indicated bond failure at the adhesive/enamel and adhesive/bracket interface. Controversy also exists among different studies in this respect; some studies reported bond failure at the adhesive/enamel interface [16,20] while others reported failure at the adhesive/bracket interface [14,15]. The following reasons may explain this variation in results:
1. Different methods for ARI analysis(evaluation of enamel surface versus base of bracket)
2. Different location of force exertion or different angulations of blade during SBS testing
3. Different methodsof enamel surface conditioning before bonding
4. variable types of adhesives and brackets used [24]. Profit introduced the adhesive/bracket interface to be the favorable region for bracket debonding because the risk of enamel damage would be minimal if bracket debonding occurs at this interface. Furthermore, in case of accidental bracket debonding, RMGIC remnants on the conditioned tooth surface would continue to release fluoride [19]. However, this method of debonding has the disadvantage of requiring more chairside time for adhesive remnant removal after bracket debonding. In our study, adding 2% NZnO or 5% NHA to RMGIC had no significant effect on SBS. Most clinical studies are time consuming and costly; thus, it is recommended to evaluate material characteristics under in vitro conditions to obtain an overall estimate before conducting in vivo studies. Due to the presence of significant differences between oral and clinical conditions, we cannot fully generalize the results of in vitro studies to the clinical setting.

Therefore, future studies are required to evaluate the properties of RMGICs containing 2% NZnO and 5% NHA in the clinical setting.

Conclusion
1. In this study, the amount of SBS was similar among all groups.
2. RMGICs can be as effective as composite resins for bonding of metal brackets to enamel surfaces.
3. Adding 2% NZnO and 5% NHA particles to RMGICs had no negative effect on their SBS in comparison with composite resin.
In all groups, less than half of the adhesive remained on the enamel surface after bond failure.
